Abstract. Oil shale mining and processing industry in Estonia produce a wide assortment of waste could be considered as available fill materials. Waste rock which is not usable in civil engineering and road building may be used for backfilling underground mines. Paste fills technology, which has several benefits, requires careful selection of oil shale waste rock aggregates and other carbonate stones. The laboratory tests and theoretical investigations were made for determination the applicability of limestone and dolostone aggregates as backfill material. It enables to determine the feasible parameters of aggregates from oil shale mining waste rock. Analysis showed that limestone aggregates of Estonian oil shale mines suit best for backfill technology in conditions.

Keywords – oil shale industry, backfill technology, paste fill, fill materials, limestone and dolostone aggregate, geometrical parameters of aggregates.

I INTRODUCTION

The oil shale industry of Estonia provides a significant contribution to the country’s economy, but causes a large number of different problems [15][16]. Oil shale is used as a fuel for producing energy and shale oil [10][20]. Oil shale mining is performed by using a room-and-pillar method with blasting [11][16][17][18]. It is cheap, highly productive and easily mechanized. Unfortunately, if the depth of excavation is over 60 m (mine Estonia) the loss in pillars increases up to 40% [19]. On the other hand, there are problems of use or bury the waste in landfill due to large amount of neutral (limestone) and hazardous (ash) waste generated by oil shale industry. Underground oil shale mining is performed by using a room-and-pillar method with blasting [11][16][17][18]. It is cheap, highly productive and easily mechanized. Unfortunately, if the depth of excavation is over 60 m (mine Estonia) the loss in pillars increases up to 40% [19]. On the other hand, there are problems of use or bury the waste in landfill due to large amount of neutral (limestone) and hazardous (ash) waste generated by oil shale industry.

Underground oil shale mining is performed by using a room-and-pillar method with blasting [11][16][17][18]. It is cheap, highly productive and easily mechanized. Unfortunately, if the depth of excavation is over 60 m (mine Estonia) the loss in pillars increases up to 40% [19]. On the other hand, there are problems of use or bury the waste in landfill due to large amount of neutral (limestone) and hazardous (ash) waste generated by oil shale industry. It requires careful selection of fill materials, including limestone aggregates. Past fills method has several benefits, most of them are crucial for the usefulness of backfill technology. On the same time there is lack in data characterizing the above mentioned waste filling materials. The choice of a proper backfill material is essential in the control of fill costs and backfill properties after placement. The main aim of these investigations was to determine the applicability of waste rock aggregates as backfill material in condition of Estonian oil shale mines.

II GEOLOGICAL SITUATION

The Estonian oil shale deposit is located in the north-eastern part of the country. The oil shale bed has a form of a flat bed slightly inclined (2 – 3 m per km) southward. The commercial oil shale bed and its immediate roof consist of oil shale and limestone seams. The main roof consists of carbonate rocks of varying thickness. Characteristics of the individual oil shale and limestone seams are rather different. The strength of the rocks increases southward. The underground mining works are going at deepness 35-65 m, but at the southern border of deposit mining deepness will grow up to 120-130 m, notable increases overburden and its pressure to pillars [8][11][16]. The thickness of commercial oil shale seam is about 2.8 m. The waste rock separated from run of mine, which proportion is approximately 40%, is suitable for production of construction and backfill material [13].

Limestone companies are mostly located in Harjumaa County. It is in the northwestern Estonia, on the southern shore of the Finnish Gulf, about 80km to south from Helsinki, Finland. Geologically this area belongs to the southern slope of the Fennoscandian shield, where the Precambrian Early Proterozoic crystalline rocks of age 2.0-1.3Ga are covered by...
sequence of the Ediacaran and Paleozoic sedimentary rocks with age between 600Ma and 359Ma in Estonia [2]. In the Harjumaa County there are being registered 16 carbonate stone deposits, four of them: Vasalemma, Harku, Nabala, and Väo are listed as deposits of all-country importance [21].

III BACKFILL TECHNOLOGY
In Estonian oil shale industry a wide assortment of fill materials is available [6][7]. The whole processing of oil shale from mining up to energy and oil generates large amount of different waste:
Separation of limestone from the raw oil shale generates large amounts of waste, which consists in 82...94 % of limestone and 6...18 % of oil shale residues. These are stockpiled in form of cones (55 m height) and total area of these piles is about 3.5 km². Limestone production is about 6.5 Mt per year.
1. The Estonian Thermal Power Plants use two different oil shale combustion technologies: pulverized firing (PF) and circulating fluidized bed combustion (CFBC) technology. The compositional and morphological variation between PF and CFBC ashes [3] are principally controlled by firing temperature differences between combustion technologies, and by grain size difference of oil shale fuel. From the point of chemistry ash from oil shale combustion is very similar to cement (with exception in alkalinity) and there is no significant difference between the potential environmental impacts from the side of oil shale ash. About 4 km² of the landfill are occupied with ash ponds. Annual production is about 5 Mt. The determination of different ashes parameters demands supplementary investigations and is under construction.
2. In modern backfill technologies paste fills are preferred [4][5]. It requires carefully selected grain-size distribution of solid particles and is able to flow without sedimentation in pipes by low water content (10...30 %). In this case backfill slurry has several benefits:
Mixtures are able to set with lower or without presence of additional binders.
Shorter binding times and better mechanical properties.
Drainage and processing of bleed water eliminated.
Consequently, at a first approximation the limestone aggregates properties determine the behavior of backfill. Oil shale waste rock (limestone) is produced during extraction as reject material from separation plant and material from crushing and sizing operations in aggregate production. It became clear that production of aggregate produces large amount of non-commercial aggregate [13].

IV GEOMETRICAL PARAMETERS OF AGGREGATES
The porosity of fill material consists of the void spaces between solid fragments. If the fragments are solid spheres of equal diameters the cubic and rhombohedral pacing is possible (see Fig. 1) [1].

![Fig. 1. Packing of the solid fragments](image)

A. Uniformity Coefficient
The uniformity coefficient of a material is a measure of how well or poorly sorted it is. It is presented by following formula[1]:

\[ C_u = \frac{d_{60}}{d_{10}} \]  \( (1) \)

where \( C_u \) – uniformity coefficient; \( d_{60} \) – grain size that is 60% finer by weight; \( d_{10} \) – the grain size that is 10% finer by weight.

A sample with a uniformity coefficient less than 4 is well sorted, if it is more than 6 it is poorly sorted [1].

The grain-size distribution curve and uniformity coefficients for aggregate sizes 4/16, 16/32 and 32/63 mm have been determined. Fig. 2 demonstrates the
grain-size distribution curve for aggregate size 16/32 mm, mine Estonia.

Investigation showed that uniformity coefficient for all aggregate sizes is less than 4. For limestone and dolostone uniformity coefficient is less than 3. Consequently, the above mentioned aggregates are well sorted and they satisfy the paste fills requirement.

B. Shape of the Coarse Aggregate

Flakiness Index is the percentage by weight of particles in it, whose least dimension is less than 0.6 of its mean dimension. Flaky particles may have adverse effect on concrete mix. For instance, flaky particles tend to lower the workability of concrete mix which may impair the long-term durability. The results of flakiness index investigation in Estonian oil shale mines and open casts are presented in Table 1.

V AGGREGATE PARAMETERS FOR BACKFILLING

A complex method, including laboratory tests and theoretical investigations, were made for determination of the applicability of limestone aggregates as backfill material. The results of investigations are presented in Table 2.

VI RESULTS

In Estonian oil shale industry a wide assortment of fill materials is available. In modern backfill technologies paste fills are preferred. It required careful selection of limestone aggregates as a component part in fill mixture and is able to flow without sedimentation in pipes by low water content. The general parameters for paste fills technology are porosity, uniformity coefficient and shape of coarse aggregate. Getting results based on large amount of theoretical investigations and of in situ experiments.

Porosity of fill material determines the amount of power plant ash in mixture. Theoretically it is between 26 and 48% depending on packing of the solid fragments. In real conditions, the fill material contains a mixture of different grain sizes and shapes. Investigation of in situ conditions showed that it is in range of 40 – 50%, which guarantees optimum amount of ash in mixture.

Strength parameters of backfill are determined by uniformity coefficient of aggregates. It is calculated, using grain-size distribution curve. Investigation showed that uniformity coefficient is less than 4. Consequently, all the aggregates are well sorted.

Shape of coarse aggregate influences on long term durability of mixture and it is presented by flakiness index. Laboratory tests showed that flakiness index for all aggregate sizes is up to 11. If the flakiness index is less than 35%, the negative influence on the strength parameters of backfill is negligible.

Analysis showed that limestone aggregates suit best for backfill technology in conditions of Estonian oil shale mines. Usable investigation methods and getting results are applicable for different aggregates as a component part in fill mixture.
